Temperature maps of the Cosmic Microwave Background (CMB) radiation, as those obtained by the Wilkinson Microwave Anisotropy Probe (WMAP), provide one of the most precise data sets to test fundamental hypotheses of modern cosmology. One of these issues is related to the statistical properties of the CMB temperature fluctuations, which would have been produced by Gaussian random density fluctuations when matter and radiation were in thermal equilibrium in the early Universe. We analysed here the WMAP data and found that the distribution of the CMB temperature fluctuations $P^{\text{CMB}}(\Delta T)$ can be quite well fitted by the anomalous temperature distribution emerging within nonextensive statistical mechanics. This theory is based on the nonextensive entropy $S_q \equiv k\{1 - \int dx [P_q(x)]^q\}/(q-1)$, with the Boltzmann-Gibbs expression as the limit case $q \rightarrow 1$. For the frequencies investigated ($\nu = 40.7, 60.8$, and 93.5 GHz), we found that $P^{\text{CMB}}(\Delta T)$ is well described by $P_q(\Delta T) \propto 1/[1 + (q-1)B(\nu)\Delta T^2]^{1/(q-1)}$, with $q = 1.055 \pm 0.002$, which exclude, at the 99% confidence level, exact Gaussian temperature distributions $P^{\text{Gauss}}(\Delta T) \propto e^{-B(\nu)\Delta T^2}$, corresponding to the $q \rightarrow 1$ limit, to properly represent the CMB temperature fluctuations measured by WMAP.

Keywords: Cosmic Background Radiation: temperature fluctuations; Nonextensive statistical mechanics; Nongaussian distributions.

Cosmic Microwave Background (CMB) radiation is formed by the leftover photons from the early Universe, when matter and radiation were coupled in thermal equilibrium. With the expansion of the Universe, these photons decoupled and spread out freely throughout space, basically conserving their primordial features. In the early 90's, the Far Infrared Absolute Spectrophotometer, on board the Cosmic Background Explorer (COBE) satellite, proved that this radiation was in thermal equilibrium by measuring its Planckian spectrum, with the temperature $T_0 = 2.725 \pm 0.002$ K [1]. Although the accuracy of these data (within limits as tight as 0.03% in the frequency range 60–600 GHz) left no doubt about the past thermal equilibrium state of the CMB, it is still possible that such Planck law derived within Boltzmann-Gibbs statistics does not exactly describe this radiation and may instead obey a generalized expression. A plausible distribution could be that obtained within nonextensive statistical mechanics (for a review on this subject see, e.g. [2]), with values of the q_a -parameter ranging in the interval $|q_a - 1| \lesssim 5 \times 10^{-4}$ (a stands for *average* and refers to the quasi-Planckian distribution corresponding to T_0) as shown in [3].

Observations with another instrument on board COBE, the Differential Microwave Radiometer (COBE-DMR) [4], detected for the first time that the CMB contains tiny variations around T_0 , termed CMB temperature fluctuations ΔT , at the level of one part in 10^5 on large angular scales ($\sim 7^\circ$). Since the standard inflationary cosmology predicts that these temperature fluctuations should be isotropic and Gaussian random, the COBE-DMR data motivated a number of analyses, although not so accurate due to the large angular resolution of the data, to test the statistical properties of the CMB (see, e.g. [5]).

Recently, highly precise and excellent angular resolu-

tion data from the Wilkinson Microwave Anisotropy Probe (WMAP) [6] confirmed the existence of the CMB temperature fluctuations. The WMAP satellite observes the microwave sky in five frequency bands, K, Ka, Q, V, and W, centred on the frequencies 22.8, 33.0, 40.7, 60.8, and 93.5 GHz, respectively. The corresponding CMB maps released by the WMAP team are pixelized in the HEALPix scheme [7] with a resolution parameter $N_{\text{side}} = 512$, which means that the celestial sphere is covered with 3,145,728 equal-area pixels, with a pixel size of ~ 7 arcmin.

These highly accurate CMB data have renewed concerns over the CMB statistical properties, and considerable analyses of the Gaussian hypothesis have been done [8]. Clearly, the study of such hypothesis must take into account the possibility that deviations from Gaussianity may have non-cosmological origins such as unsubtracted foreground contamination, instrumental noise, and/or systematic effects [9]. But they may also have cosmological origin, as being, for instance, the effect of cosmic strings on CMB [10]. In a variety of analyses using different mathematical tools, and including foreground cleaning processes aimed to eliminate possible non-Gaussian contaminations, many evidences regarding deviations from Gaussianity in the WMAP CMB data have been recently reported [11] (see also [12] and references therein).

In what follows we shall perform the statistical analysis of the Q, V and W maps, after the application of the Kp0 mask to eliminate known foregrounds, in order to determine how much their distributions of temperature fluctuations deviate, if they do, from the Gaussian distribution. Then we discuss the possible account of such distributions according to the non-Gaussian temperature distribution emerging within nonextensive statistical mechanics, because gravitation is a long-range interaction and this kind of phenomenon seems to be conveniently studied in the framework of this theory [13]. Definitely, the statistical significance of our results shall be supported by the analysis of substantial Monte Carlo CMB

maps.

Now, we briefly introduce the basics of nonextensive statistical mechanics (see [14] for various applications). The probability distribution $P_q(x)$, as a function of the variable x , results from the optimization of the q -entropy defined by [2]

$$S_q \equiv k\{1 - \int dx [P_q(x)]^q\}/(q-1), \quad (1)$$

with the constraints

$$\int dx P_q(x) = 1, \quad (2)$$

$$\frac{\int dx x [P_q(x)]^q}{\int dx [P_q(x)]^q} = c_1, \quad (3)$$

$$\frac{\int dx x^2 [P_q(x)]^q}{\int dx [P_q(x)]^q} = c_2. \quad (4)$$

From this, one straightforwardly obtains

$$P_q(x) = \frac{e_q^{-\lambda_{1q}(x-c_1)-\lambda_{2q}(x^2-c_2)}}{\int dx e_q^{-\lambda_{1q}(x-c_1)-\lambda_{2q}(x^2-c_2)}}, \quad (5)$$

where λ_{1q} and λ_{2q} are related to the Lagrange multipliers, and where

$$e_q^z \equiv [1 + (1-q)z]^{1/(1-q)}, \quad \text{for } [1 + (1-q)z] \geq 0, \quad (6)$$

while $e_q^z = 0$ otherwise. Note that this distribution function P_q is the solution of a non-linear Fokker-Planck equation [15]. One observes that eq. (5) can be rewritten as follows

$$P_q(x) = \frac{e_q^{-B_q(x-x_0)^2}}{\int dx e_q^{-B_q(x-x_0)^2}} = A_q e_q^{-B_q(x-x_0)^2}, \quad (7)$$

where the values of B_q and x_0 are related to λ_{1q} and λ_{2q} ; A_q is the normalization constant obtained in such a way that eq. (2) is satisfied.

We shall now use this nonextensive distribution to account for the CMB temperature fluctuations distribution of WMAP data. In this case we have $x = T$, $x_0 = T_0$, and $B_q = B(\nu)$ (strictly speaking $B_q = B_q(\nu)$; however, for the cases considered here we have just one value for the q -parameter). Thus,

$$P_q(\Delta T) = A_q e_q^{-B(\nu)\Delta T^2}, \quad (8)$$

where we wrote $P_q(\Delta T)$ instead of $P_q(T)$ to be clear that our analysis is dealing with the statistics of the temperature fluctuations. In the limit $q \rightarrow 1$, we recover the Gaussian distribution

$$P_q \rightarrow P^{\text{Gauss}} = A e^{-B(\nu)\Delta T^2}, \quad (9)$$

where $A \equiv 1/(\sigma_\nu \sqrt{2\pi})$, $B(\nu) \equiv 1/(2\sigma_\nu^2)$, and σ_ν^2 is the variance of the Gaussian distribution. For a comparison of the distributions P_q with P^{Gauss} , in our analyses we assume $A_q = A$.

As recently pointed out by Jeong & Smoot [10], the signal measured at any pixel in the microwave sky is made of several components

$$T_{\text{pixel}} = T_{\text{foregrounds}} + T_{\text{noise}} + T_{\text{CMB}}, \quad (10)$$

corresponding to foreground signals, the noise from the instruments, and the CMB temperature fluctuations, respectively. Foreground contributions, expected to be small away from the Galactic plane and with point sources punched out,

are removed from the beginning with the application of the Kp0 mask [18]. Thus, one is left with CMB signal plus the Gaussian signal from the instrument noise (actually the signal noise is Gaussian *per* observation [10, 16]).

Thus, one has to consider these effects by defining [10] the variance of the total signal T_{pixel} as

$$\sigma_\nu^2 \equiv \sigma_{\text{pixel}}^2 = \frac{\sigma_0^2}{n_i} + \sigma_{\text{CMB}}^2, \quad (11)$$

where n_i is the number of observations for the i th pixel, σ_0^2 is the noise variance *per* observation, and σ_{CMB}^2 is the variance of the CMB temperature fluctuations. The mean contribution of the instrumental noise can be estimated by considering the effect of the different number of observations for each pixel (see Ref. [16], pag. 16). Thus, given a CMB map, this can be done with the effective variance due to noise

$$\sigma_{\text{noise}}^2(\nu) = \frac{\sigma_0^2 \sum_{i=1}^N (1/n_i)}{N}, \quad (12)$$

where σ_0^2 is the variance *per* observation characteristic of the instrument (radiometer), n_i is the effective number of observations for the i th pixel, and N is the total number of pixels considered in the analysis of the map. For the Q, V and W maps we obtained $\sum (1/n_i) = 7, 423.90, 5, 465.98$, and $1, 816.96$, respectively; moreover the number of pixels analysed N is equal for the three maps $N_Q = N_V = N_W = 2, 414, 705$. In other words, the effective noise variances $\sigma_{\text{noise}}^2(\nu)$ and the variances σ_ν^2 leads to the CMB variance

$$\sigma_{\text{CMB}}^2 = \sigma_\nu^2 - \sigma_{\text{noise}}^2(\nu). \quad (13)$$

Although both σ_ν^2 and $\sigma_{\text{noise}}^2(\nu)$ depend on the map under analyses, their difference is independent of the map, in other words, if our treatment of instrumental noise is correct, the CMB variance σ_{CMB}^2 should be the same for the three CMB maps under investigation (Q, V, and W).

As previously reported (see section 2.2 and Fig. 2 in Ref. [10]) the WMAP CMB temperature distribution does not fully obey a Gaussian temperature distribution

$$P^{\text{Gauss}}(\Delta T) = \frac{1}{\sigma_\nu \sqrt{2\pi}} e^{-(1/2\sigma_\nu^2)\Delta T^2}. \quad (14)$$

In fact, the deviation from a Gaussian distribution can be appreciated in Figs. 1a, 1c, and 1e, for the Q, V, and W maps, respectively. In our analyses, the best-fit Gaussian to the data was obtained according to the $\chi^2/\text{degree of freedom (dof)}$ estimator test. Thus, the $\chi^2/200$ values for the Gaussian fits are 0.116, 0.275, and 0.167, for the Q, V and W maps, respectively, and the $\chi^2/200$ values for the nonextensive temperature distribution P_q are 0.00155, 0.00178, and 0.00216, for the Q, V and W maps, respectively. Analyses performed using 400 dof instead of 200 dof result in similar estimative values.

In Fig. 1 the blue lines correspond to the best-fit Gaussian with variances $\sigma_Q = 140.58\mu\text{K}$, $\sigma_V = 163.52\mu\text{K}$, and $\sigma_W = 190.35\mu\text{K}$, while the red lines correspond to the best nonextensive distribution fit with the same variances and $q = 1.056$. Once the variances σ_ν^2 have been determined through the χ^2 best-fit Gaussian temperature distribution, for each of the CMB maps, then we use the effective noise variance σ_{noise}^2 given in eq. (12) again for each of the CMB maps, to calculate the CMB variance. Our results are $\sigma_{\text{CMB}}^2 =$

$(68.77)^2$, $(69.34)^2$, $(68.81)^2 \mu\text{K}^2$, for the Q, V, and W maps, respectively, in excellent agreement with what is expected. This result validates the effective noise variance as representing the mean contribution of the instrumental noise.

In Figs. 1a, 1c, and 1e we plotted the temperature distributions of the Q, V, and W maps, in the form $\log_{10}(P^{\text{CMB data}})$, $\log_{10}(P^{\text{Gauss}})$, and $\log_{10}(P_q)$ versus ΔT using the χ^2 best-fit Gaussian temperature distribution P^{Gauss} and also the best-fit nonextensive distributions P_q with $q = 1.056$. To enhance the non-Gaussian behavior of the WMAP data, in Figs. 1b, 1d, and 1f, we plotted instead $\log_{10}(P^{\text{CMB data}})$, $\log_{10}(P^{\text{Gauss}})$, and $\log_{10}(P_q)$ versus $(\Delta T/\sigma_\nu)^2$, since linearity (blue curves) corresponds to the best-fit Gaussian distribution. Our results evidence that the distribution of the CMB temperature fluctuations does not obey a Gaussian distribution.

In order to strengthen our analysis, we removed fits to the WMAP foreground templates for the eight individual radiometer maps (corresponding to radiometers Q1, Q2, V1, V2, W1, W2, W3, and W4), after applying the Kp0 mask to avoid high latitude foregrounds. Our results are plotted in Fig. 2. As observed, these results were essentially the same as those shown in Fig. 1, that is, $q = 1.055 \pm 0.002$.

Then, we investigated the possibility that the discrepancies observed between WMAP data and exact Gaussian distributions, as evidenced in Figs. 1 and 2, occur just by chance. For this scope, we analysed a set of 10,000 Monte Carlo realizations of CMB Gaussian maps, and we found, at the 99% confidence level (CL), that the distributions of CMB temperature fluctuations measured by WMAP are not properly described by exact Gaussian temperature distributions.

We also investigated, through substantial numerical simulations, the possibility that the instrumental noise could introduce non-Gaussian signals in the CMB maps. According to [10, 16] instrument noise produces a random Gaussian signal, actually Gaussian *per* observation. Since pixels are observed a different number of times, the effect on the CMB map could be a significant non-Gaussian signal in the CMB temperature distribution, and clearly this possibility should be taken into account in the simulations. For this, to each one of the 10,000 Monte Carlo CMB Gaussian maps we added a simulated non-stationary Gaussian radiometer noise, taking into account the actual number of observations (n_i) for each pixel in the maps. We consider the n_i data from the WMAP-W4 map [6]. We obtained $q = 1.005 \pm 0.01$ for the CMB plus non-stationary Gaussian noise simulated maps, which is obviously consistent with Gaussianity. A χ^2 estimator test shows that the $P_q(\Delta T)$ does not fit the simulated data as well as it does the WMAP data. The monotonic discrepancy behavior observed in Figs. 1b, 1d, and 1f, which is well fitted by the nonextensive expression given in eq. (7) due to a minimum χ^2 value, was observed in less than 1% of the simulations performed. Therefore we can rule out, at the 99% CL, the simulated radiometer noise as being the explanation for the non-Gaussianity observed in the WMAP temperature fluctuations.

In conclusion, we have shown that an exact Gaussian distribution is excluded, at the 99% CL, to properly represent the CMB temperature fluctuations measured by WMAP. Although the value of the q -parameter is close to 1, our analyses indicate that to consider these temperature fluctuations as being of Gaussian nature is not rigorously exact and it should be considered as a good approximation instead.

- [18] The Q, V, and W maps here analysed were already corrected by the WMAP team for the Galactic foregrounds (synchrotron, free-free, and dust emission) using the 3-band, 5-parameter template fitting method described in [17]. However, the foreground removal is only applicable to regions outside the Kp2 mask. For this, the Kp2 mask, or preferably the Kp0 mask, should be applied for the statistical analysis of the CMB maps.

FIG. 2: Results of the analysis of WMAP data using the individual radiometer maps Q1, Q2, V1, V2, W1, W2, W3, and W4, after applying the Kp0 mask. In all plots the blue curve represents the best-fit Gaussian, according to the χ^2 estimator, while the red curve represents the best nonextensive distribution function. Each P_q distributions fits the corresponding data with a slightly different value of q , where the mean value of them is $q = 1.055 \pm 0.002$.
